Intro to R Statistics

Summary

- ggplot() specifies what data use and what variables will be mapped to where
- inside ggplot(), mapping = aes(x = , y = , color =) specify what variables correspond to what aspects of the plot in general
- · layers of plots can be combined using the + at the **end** of lines
- use geom_line() and geom_point() to add lines and points
- sometimes you need to add a group element to mapping = aes() if your plot looks strange
- make sure you are plotting what you think you are by checking the numbers!
- facet_grid(~ variable) and facet_wrap(~variable) can be helpful to quickly split up your plot

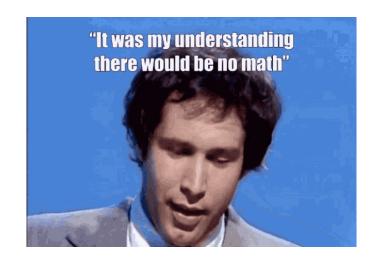

Summary

- the factor class allows us to have a different order from alphanumeric for categorical data
- we can change data to be a factor variable using mutate, the as_factor()
 (of forcats package) or factor() function and specifying the levels with the
 levels argument
- the fct_reorder({variable_to_reorder}, {variable_to_order_by})
 helps us reorder a variable by the values of another variable
- arranging, tabulating, and plotting the data will reflect the new order

Overview

We will cover how to use R to compute some of basic statistics and fit some basic statistical models.

- Correlation
- T-test
- Linear Regression / Logistic Regression

Overview

We will focus on how to use R software to do these. We will be glossing over the statistical theory and "formulas" for these tests. Moreover, we do not claim the data we use for demonstration meet assumptions of the methods.

There are plenty of resources online for learning more about these methods, as well as dedicated Biostatistics series (at different advancement levels) at the JHU School of Public Health.

Check out www.opencasestudies.org for deeper dives on some of the concepts covered here and the resource page for more resources.

Correlation

Correlation

Function cor() computes correlation in R

```
cor(x, y = NULL, use = "everything",
   method = c("pearson", "kendall", "spearman"))
```

- provide two numeric vectors (arguments x, y), or
- provide a data.frame / tibble with numeric columns only
- by default, Pearson correlation coefficient is computed

Correlation

library(jhur)

Correlation for two vectors

First, we compute correlation by providing two vectors.

Like other functions, if there are NAs, you get NA as the result. But if you specify use only the complete observations, then it will give you correlation using the non-missing data.

```
x <- circ %>% pull(orangeAverage)
y <- circ %>% pull(purpleAverage)

cor(x, y)

[1] NA

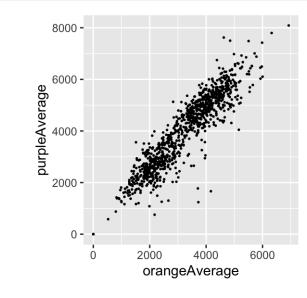

cor(x, y, use = "complete.obs")

[1] 0.9195356
```

Correlation for two vectors with plot

In plot form...

```
circ %>%
  ggplot(aes(x = orangeAverage, y = purpleAverage)) +
  geom_point(size = 0.3)
```

Correlation for data frame columns

0.5447031

We can compute correlation for all pairs of columns of a data frame / matrix. We typically just say, "compute correlation matrix".

Columns must be all numeric!

bannerAverage

```
circ subset Average <- circ %>% select(ends with("Average"))
dim(circ_subset_Average)
[1] 1146
           4
cor_mat <- cor(circ_subset_Average, use = "complete.obs")</pre>
cor mat
             orangeAverage purpleAverage greenAverage bannerAverage
                                                          0.5447031
orangeAverage
                 1.0000000

Correlation for data frame columns with plot

Google, "r correlation matrix plot"

```
library(corrplot)
corrplot(cor_mat, type = "upper", order = "hclust")
```

T-test

T-test

The commonly used are:

- one-sample t-test used to test mean of a variable in one group
- two-sample t-test used to test difference in means of a variable between two groups (if the "two groups" are data of the same individuals collected at 2 time points, we say it is two-sample paired t-test)

The t.test() function in R is one to address the above.

Running one-sample t-test

x <- circ %>% pull(orangeAverage)

It tests mean of a variable in one group. By default (i.e., without us explicitly specifying values of other arguments):

- tests whether a mean of a variable is equal to 0 (mu=0)
- uses "two sided" alternative (alternative = "two.sided")
- returns result assuming confidence level 0.95 (conf.level = 0.95)

```
t.test(x)

One Sample t-test

data: x
t = 83.279, df = 1135, p-value < 0.00000000000000000022
alternative hypothesis: true mean is not equal to 0
95 percent confidence interval:
   2961.700 3104.622
sample estimates:
mean of x
   3033.161</pre>
```

Running two-sample t-test

It tests test difference in means of a variable between two groups. By default:

- tests whether difference in means of a variable is equal to 0 (mu=0)
- uses "two sided" alternative (alternative = "two.sided")
- returns result assuming confidence level 0.95 (conf.level = 0.95)
- assumes data are not paired (paired = FALSE)
- assumes true variance in the two groups is not equal (var.equal = FALSE)

```
x <- circ %>% pull(orangeAverage)
y <- circ %>% pull(purpleAverage)
t.test(x, y)
```

Welch Two Sample t-test

```
data: x and y
t = -17.076, df = 1984, p-value < 0.000000000000000022
alternative hypothesis: true difference in means is not equal to 0
95 percent confidence interval:
   -1096.7602  -870.7867
sample estimates:
mean of x mean of y
3033.161  4016.935</pre>
```

T-test: retrieving information from the result with **broom** package

The broom package has a tidy() function that can organize results into a data frame so that they are easily manipulated (or nicely printed)

P-value adjustment

You run an increased risk of Type I errors (a "false positive") when multiple hypotheses are tested simultaneously.

Use the p.adjust() function on a vector of p values. Use method = to specify the adjustment method:

```
my_pvalues <- c(0.049, 0.001, 0.31, 0.00001)
p.adjust(my_pvalues, method = "BH") # Benjamini Hochberg

[1] 0.06533333 0.00200000 0.31000000 0.00004000

p.adjust(my_pvalues, method = "bonferroni")

[1] 0.19600 0.00400 1.00000 0.00004</pre>
```

Some other statistical tests

- wilcox.test() Wilcoxon signed rank test, Wilcoxon rank sum test
- shapiro.test() Shapiro test
- · ks.test() Kolmogorov-Smirnov test
- var.test() Fisher's F-Test
- chisq.test() Chi-squared test
- aov() Analysis of Variance (ANOVA)

Regression

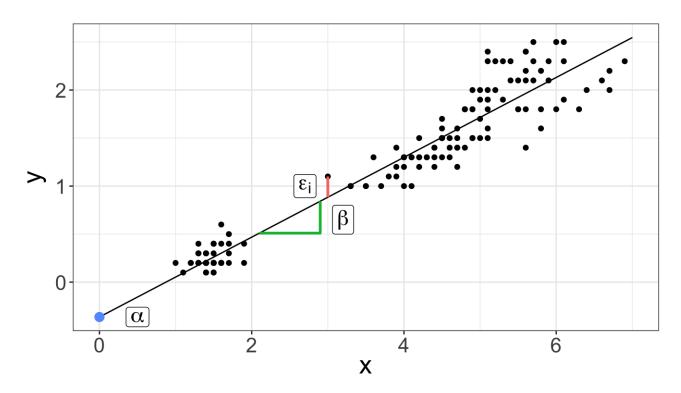

Linear regression is a method to model the relationship between a response and one or more explanatory variables.

We provide a little notation here so some of the commands are easier to put in the proper context.

$$y_i = \alpha + \beta x_i + \varepsilon_i$$

where:

- · y_i is the outcome for person i
- α is the intercept
- β is the slope
- $\cdot \; x_i$ is the predictor for person i
- ε_i is the residual variation for person i

Linear regression is a method to model the relationship between a response and one or more explanatory variables.

We provide a little notation here so some of the commands are easier to put in the proper context.

$$y_i = \alpha + \beta_1 x_{i1} + \beta_2 x_{i2} + \beta_3 x_{i3} + \varepsilon_i$$

where:

- · y_i is the outcome for person i
- α is the intercept
- \cdot β_1 , β_2 , β_2 are the slopes for variables x_{i1} , x_{i2} , x_{i3}
- $\cdot \;\; x_{i1}$, x_{i2} , x_{i3} are the predictors for person i
- · $arepsilon_i$ is the residual variation for person i

Linear regression fit in R

To fit regression models in R, we use the function glm() (Generalized Linear Model).

We typically provide two arguments:

- formula model formula written using names of columns in our data
- · data our data frame

Linear regression fit in R: model formula

Model formula

$$y_i = \alpha + \beta x_i + \varepsilon_i$$

In R translates to

Linear regression fit in R: model formula

Model formula

$$y_i = \alpha + \beta x_i + \varepsilon_i$$

In R translates to

In practice, y and x are replaced with the names of columns from our data set.

For example, if we want to fit a regression model where outcome is income and predictor is years_of_education, our formula would be:

Linear regression fit in R: model formula

Model formula

$$y_i = \alpha + \beta_1 x_{i1} + \beta_2 x_{i2} + \beta_3 x_{i3} + \varepsilon_i$$

In R translates to

$$y \sim x1 + x2 + x3$$

In practice, y and x1, x2, x3 are replaced with the names of columns from our data set.

For example, if we want to fit a regression model where outcome is income and predictors are years_of_education, age, location then our formula would be:

income ~ years_of_education + age + location

We will use data about emergency room doctor complaints.

"Data was recorded on 44 doctors working in an emergency service at a hospital to study the factors affecting the number of complaints received."

```
# install.packages("faraway")
library(faraway)

data(esdcomp)
esdcomp
```

Linear regression: model fitting

We fit linear regression model with the number of patient visits (visits) as an outcome and total number of hours worked (hours) as a predictor.

Linear regression: model summary

The summary() function returns a list that shows us some more detail

```
summary(fit)
Call:
glm(formula = visits ~ hours, data = esdcomp)
Deviance Residuals:
            10 Median 30
   Min

```

Linear regression: factors

Factors get special treatment in regression models - lowest level of the factor is the comparison group, and all other factors are relative to its values.

residency takes values Y or N to indicate whether the doctor is a resident.

esdcomp %>% count(residency)

```
residency n
1 N 24
2 Y 20
```

Linear regression: factors

```
fit_3 <- glm(visits ~ residency, data = esdcomp)</pre>

Generalized Linear Models (GLMs)

Generalized Linear Models (GLMs) allow for fitting regressions for non-continuous/normal outcomes. Examples include: logistic regression, Poisson regression.

Add the **family** argument – a description of the error distribution and link function to be used in the model. These include:

- binomial(link = "logit")
- poisson(link = "log"), and other.

See ?family documentation for details of family functions.

Logistic regression

We will use data about breast cancer tumors.

"The purpose of this study was to determine whether a new procedure called fine needle aspiration which draws only a small sample of tissue could be effective in determining tumor status."

Logistic regression

Class is a 0/1-valued variable indicating if the tumor was malignant (0 if malignant, 1 if benign).

```
binom_fit <- glm(Class ~ UShap + USize, data = wbca, family = binomial())</pre>
summary(binom_fit)

Odds ratios

This data shows whether people became ill after eating ice cream in the 1940s.

```
head(ice_cream)
  ill vanilla.ice.cream
    1
1
1
ice_cream %>% count(ill, vanilla.ice.cream)
  ill vanilla.ice.cream
    0
                        0 18
    0
1
1
                        1 11
                        1 43
```

Odds ratios

attr(,"method")

Use oddsratio(x, y) from the epitools() package to calculate

```
library(epitools)
response <- ice_cream %>% pull(ill)
predictor <- ice_cream %>% pull(vanilla.ice.cream)
oddsratio(predictor, response)
$data
        Outcome
Predictor 0 1 Total

```

Final note

Some final notes:

- Researcher's responsibility to understand the statistical method they use underlying assumptions, correct interpretation of method results
- Researcher's responsibility to understand the R software they use meaning of function's arguments and meaning of function's output elements

Summary

- Use cor() to calculate correlation between two vectors. corrplot() is nice for a quick visualization!
- t.test() tests the difference in means between two vectors
- glm() fits regression models:
 - Use the formula = argument to specify the model (e.g., y ~ x or y ~ x1
 + x2 using column names)
 - Use data = to indicate the dataset
 - Use family = binomial() to do a logistic regression
 - summary() gives useful statistics
- oddsratio() from the epitools package can calculate odds ratios
- this is just the tip of the iceberg!

Adding correlation value to a plot

Note that you can add the correlation value to a plot, via the annotate().

```
cor_val <- cor(x, y, use = "complete.obs")
cor_val_label <- paste0("r = ", round(cor_val, 3))

circ %>%
    ggplot(aes(x = orangeAverage, y = purpleAverage)) +
    geom_point(size = 0.3) +
    annotate("text", x = 2000, y = 7500, label = cor_val_label, size = 5)
```
